Agenda

In a Nutshell

Outline

In a Nutshell

Liveness Properties

- characteristics of algorithms for **non-blocking synchronisation**

Liveness Properties

- characteristics of algorithms for **non-blocking synchronisation**:

  obstruction-free
  - if any process eventually in isolation (i.e., absence of simultaneously interacting processes) can complete any operation in a finite number of steps [2]
  - prone to **starvation** of conflicting processes

Liveness Properties

- characteristics of algorithms for **non-blocking synchronisation**:

  lock-free
  - if "some process will complete an operation in a finite number of steps, regardless of the relative speeds of the processes" [1, p. 142][1]
  - free of **starvation** of at least one conflicting process

[1] Originally, also referred to as "nonblocking".

Liveness Properties

- characteristics of algorithms for **non-blocking synchronisation**:

wait-free

- if "any process can complete any operation in a finite number of steps, regardless of the relative speeds of the other processes" [1, p. 7]
- free of starvation of any conflicting process

Liveness Properties

- characteristics of algorithms for **non-blocking synchronisation**:
  - obstruction-free
    - if any process eventually in isolation (i.e., absence of simultaneously interacting processes) can complete any operation in a finite number of steps [2]
    - prone to **starvation** of conflicting processes
  - lock-free
    - if "some process will complete an operation in a finite number of steps, regardless of the relative speeds of the processes" [1, p. 142][1]
    - free of **starvation** of at least one conflicting process
  - wait-free
    - if "any process can complete any operation in a finite number of steps, regardless of the relative speeds of the other processes" [1, p. 7]
    - free of starvation of any conflicting process
- all, no process can be blocked by delays or failures of other processes
  - that is to say, any of these procedures ensures **deadlock freedom**

[1] Originally, also referred to as "nonblocking".

Transactional Computation I

```
1  word_t any;                                  /* shared data */
2  {
3      word_t old, new;                         /* own data */
4      do new = compute(old = any);             /* read */
5      while (!CAS(&any, old, new));            /* validate/write */
6  }
```

Transactional Computation I

```
1  word_t any;                                  /* shared data */
2  {
3      word_t old, new;                         /* own data */
4      do new = compute(old = any);             /* read */
5      while (!CAS(&any, old, new));            /* validate/write */
6  }
```

- at a first glance, this looks like lock-free progress guarantee:
  - CAS ensures that one out of possibly many conflicting processes succeeds
  - yet, which one is not determined and process overhauling[2] is facilitated

[2] A desirable property given priority-based process scheduling.

Transactional Computation I

```
1  word_t any;                                  /* shared data */
2  {
3      word_t old, new;                         /* own data */
4      do new = compute(old = any);             /* read */
5      while (!CAS(&any, old, new));            /* validate/write */
6  }
```

- at a first glance, this looks like lock-free progress guarantee:
  - CAS ensures that one out of possibly many conflicting processes succeeds
  - yet, which one is not determined and process overhauling[2] is facilitated
- however, a closer look may even reveal only obstruction freedom:
  - progress guarantee stands and falls with the properties of *compute*

    stands – lock-free if *compute* is either lock- or wait-free

    falls – off to obstruction-free if *compute* is obstruction-free
  - thus, the likewise weaker property of *compute* comes out on top

[2] A desirable property given priority-based process scheduling.

```
1  word_t any;                                  /* shared data */
2  {
3      word_t old, new;                         /* own data */
4      do new = compute(old = any);             /* read */
5      while (!CAS(&any, old, new));            /* validate/write */
6  }
```

- at a first glance, this looks like lock-free progress guarantee:
  - CAS ensures that one out of possibly many conflicting processes succeeds
  - yet, which one is not determined and process overhauling[2] is facilitated
- however, a closer look may even reveal only obstruction freedom:
  - progress guarantee stands and falls with the properties of *compute*

    stands – lock-free if *compute* is either lock- or wait-free

    falls – off to obstruction-free if *compute* is obstruction-free
  - thus, the likewise weaker property of *compute* comes out on top
- strengthening of the progress guarantee at a higher level is illusionary
  - without willingness to break abstraction or black-box reuse, resp., down

[2] A desirable property given priority-based process scheduling.

Transactional Computation II

```
1  word_t any;                                  /* shared data */
2  {
3      word_t new;                              /* own data */
4      do new = compute(LL(&any));              /* read */
5      while (!SC(&any, new));                  /* validate/write */
6  }
```

```
1  word_t any;                                  /* shared data */
2  {
3      word_t new;                              /* own data */
4      do new = compute(LL(&any));              /* read */
5      while (!SC(&any, new));                  /* validate/write */
6  }
```

- at a first glance, the progress guarantee is the same as before (p. 5):
  - SC ensures that one out of possibly many conflicting processes succeeds
  - also, the likewise weaker property of *compute* comes out on top

Transactional Computation II

```
1  word_t any;                                  /* shared data */
2  {
3      word_t new;                              /* own data */
4      do new = compute(LL(&any));              /* read */
5      while (!SC(&any, new));                  /* validate/write */
6  }
```

- at a first glance, the progress guarantee is the same as before (p. 5):
  - SC ensures that one out of possibly many conflicting processes succeeds
  - also, the likewise weaker property of *compute* comes out on top
- however, a closer look may even reveal a further dependency:

LL
- besides reading from memory, typically performs two actions:
  - i make a reservation for a hardware-dependent address range
  - ii as the case may be, remember the effective address of the location

SC
- if a reservation exists, overwrite the addressed location
  - if applicable, only if the applied address matches the remembered one
- in any case, cancel a possibly existing reservation

Transactional Computation II

```
1  word_t any;                                  /* shared data */
2  {
3      word_t new;                              /* own data */
4      do new = compute(LL(&any));              /* read */
5      while (!SC(&any, new));                  /* validate/write */
6  }
```

- at a first glance, the progress guarantee is the same as before (p. 5):
  - SC ensures that one out of possibly many conflicting processes succeeds
  - also, the likewise weaker property of *compute* comes out on top
- however, a closer look may even reveal a further dependency:
  - LL
    - besides reading from memory, typically performs two actions:
      - i make a reservation for a hardware-dependent address range
      - ii as the case may be, remember the effective address of the location
  - SC
    - if a reservation exists, overwrite the addressed location
      - if applicable, only if the applied address matches the remembered one
    - in any case, cancel a possibly existing reservation
- plain sequences of LL/SC may be obstruction-free, only (cf. p. 12)
  - **exceptions** (i.e., traps/interrupts) may or may not cancel reservations
  - similar may hold for specific ("manually ejected") memory operations

Table-Based Scheduling I

- bear in mind that each process also acts as a "***feeder***" of a CPU core
  - normally, a process releases its processor either voluntarily or involuntarily
  - it either blocks or yields, or it gets the processor revoked (preemption)

Table-Based Scheduling I

- bear in mind that each process also acts as a "***feeder***" of a CPU core
  - normally, a process releases its processor either voluntarily or involuntarily
  - it either blocks or yields, or it gets the processor revoked (preemption)
- each feeder takes the scheduling decision in a finite number of steps:

```
1  process_t *elect(hoard_t *vain) {
2      process_t *next;
3
4      for (next = being(0); next < being(NPROC); next++) {
5          if (next->state != READY)
6              continue;
7
8          if (CAS(&next->state, READY, READY | PENDING))
9              return next;
10     }
11
12     return 0;
13 }
```

- the scheduling loop is **bounded** by the number of process descriptors

Table-Based Scheduling II

```
1  int cause(event_t *this) {
2      process_t *next;
3      int done = 0;
4
5      while ((next = uncage(&this->wait))) {
6          next->merit = being(ONESELF)->name;
7          next->state = READY;
8          done += 1;
9      }
10
11     return done;
12 }
```

uncage

- attempt to *purge* a chain item from the queue-based per-event waitlist $\rightsquigarrow$ lock-free semantics in case of [3, p. 30]
- if succeeded, coerce the pointer to the purged chain item into the pointer to the enclosing process descriptor (cf. p. 13)

Table-Based Scheduling II

```
1  int cause(event_t *this) {
2      process_t *next;
3      int done = 0;
4
5      while ((next = uncage(&this->wait))) {
6          next->merit = being(ONESELF)->name;
7          next->state = READY;
8          done += 1;
9      }
10
11     return done;
12 }
```

uncage

- attempt to *purge* a chain item from the queue-based per-event waitlist $\rightsquigarrow$ lock-free semantics in case of [3, p. 30]
- if succeeded, coerce the pointer to the purged chain item into the pointer to the enclosing process descriptor (cf. p. 13)

- even in case of a wait-free *purge*, the schedule loop is **unbounded**
  - a former uncaged process may have been dispatched in the meantime
  - $\hookrightarrow$ assume that the process blocks on the same event while signalling (*cause*)

Table-Based Scheduling III

```
1  int cause(event_t *this) {
2      process_t *next;
3      int done = 0;
4
5      while ((done < N) && (next = uncage(&this->wait))) {
6          next->merit = being(ONESELF)->name;
7          next->state = READY;
8          done += 1;
9      }
10
11     return done;
12 }
```

- a WCET[3] of the schedule loop is given only with a wait-free *purge*
  - in that case: $WCET(loop) \leq N \times WCET(purge)$, thus bounded

[3] *worst-case execution time*

Table-Based Scheduling III

```
1  int cause(event_t *this) {
2      process_t *next;
3      int done = 0;
4
5      while ((done < N) && (next = uncage(&this->wait))) {
6          next->merit = being(ONESELF)->name;
7          next->state = READY;
8          done += 1;
9      }
10
11     return done;
12 }
```

- a WCET[3] of the schedule loop is given only with a wait-free *purge*
  - in that case: $WCET(loop) \leq N \times WCET(purge)$, thus bounded
- but in case of a lock-free *purge*, the schedule loop is lock-free also
  - a lock-free *purge* implies a **possibly unbounded** latency until returning

[3] *worst-case execution time*

Table-Based Scheduling III

```
1  int cause(event_t *this) {
2      process_t *next;
3      int done = 0;
4
5      while ((done < N) && (next = uncage(&this->wait))) {
6          next->merit = being(ONESELF)->name;
7          next->state = READY;
8          done += 1;
9      }
10
11     return done;
12 }
```

- a WCET[3] of the schedule loop is given only with a wait-free *purge*
  - in that case: $WCET(loop) \leq N \times WCET(purge)$, thus bounded
- but in case of a lock-free *purge*, the schedule loop is lock-free also
  - a lock-free *purge* implies a **possibly unbounded** latency until returning
- last but not least, similar holds in case of an obstruction-free *purge*...

[3] *worst-case execution time*

Table-Based Scheduling IV

- each signaller takes the scheduling decision in a finite number of steps

```
1  int cause(event_t *this) {
2      process_t *next;
3      int done = 0;
4
5      for (next = being(0); next < being(NPROC); next++) {
6          if (next->event != this)
7              continue;
8
9          if (CAS(&next->event, this, 0)) {
10             next->merit = being(ONESELF)->name;
11             next->state = READY;
12             done += 1;
13         }
14     }
15
16     return done;
17 }
```

- the scheduling loop is **bounded** by the number of process descriptors

LL/SC Shallows

Alpha
- if the effective addresses are not within the same naturally aligned 16-byte section, the sequence may fail or succeed
- a reservation on a particular processor can be arbitrarily canceled by unspecified events on another processor
- if any other memory access is executed on the given processor in between, the sequence may always fail on some implementations
- a timer interrupt always cancels an existing reservation

MIPS
- a load, store, or prefetch event executed on the issuing processor may cause the sequence to fail or succeed
- the largest cache line in use determines the reservation granularity

PPC6
- the reservation granularity is implementation-dependent
- exceptions (traps/interrupts) hold up an existing reservation
- a conditional store to a "scratch" address cancels the reservation

PPC8
- ditto, but the processor grants stores only to the reserved address

If a reservation endures exceptional situations and the processor does not compare with the reservation address, the operating system must cancel the reservation in those cases.

Process-Type Coercion

```
1  inline void *coerce(void *ptr, int val) {
2    return (void *)((unsigned)ptr - val);
3  }

4  inline process_t *uncage(waitlist_h *list) {
5    chain_t *item = purge_lfs((queue_t *)list);
6
7    if (item)
8      item = coerce(item, (int)&((process_t *)0)->event);
9
10   return (process_t *)item;
11 }
```
